BIOFUEL POTENTIALS IN THE EU

Boyan Kavalov

January 2004

Report EUR 21012 EN

PREFACE

This report represents an integral part of the overall research activity of IPTS in the field of alternative fuels for transport. Building on the findings from previous IPTS studies: “Techno-economic analysis of Bio-diesel production in the EU: a short summary for decision-makers” [15], “Techno-economic analysis of Bio-alcohol production in the EU: a short summary for decision makers”, [16], “Biofuel production potential of EU-candidate countries“ – Final Report [17] and Addendum to the Final Report [18], this report investigates the internal production potential of the EU for transport biofuel under different assumptions.

This report has been written by B. Kavalov. Significant contribution to the report has been given by Antonio Soria (IPTS). Other contributors were Dimitris Papageorgiou (Q-Plan, Thessaloniki / Greece, formerly – Atlantis Consulting S.A., Thessaloniki / Greece) and Peder Jensen [European Environmental Agency (EEA), Copenhagen / Denmark, formerly – IPTS].

TABLE OF CONTENT

List of used abbreviations

k – Thousand

M – Million

BD – Biodiesel

BE – Bioethanol

BF – Biofuel(s)

DG – Directorate-General of the European Commission

EC – European Commission

EU – European Union

FD – Fossil Diesel

FF – Fossil Fuel(s)

FG – Fossil Gasoline

GJ – Giga Joule

ha – Hectare

l - litre

MJ – Mega Joule

t – ton (1 ton = 1000 kg.)

Mtoe – Million tons oil equivalent

EXECUTIVE SUMMARY

The European Commission has identified biofuels as an energy carrier that can contribute to the security and diversity of energy supply for the EU transport in an environmentally friendly way. In this context, the Directive 2003/30/EC of the European Parliament and the Council set up target shares of biofuels on the EU transport fuel market by 2010. Their reference values are 2% by the end of 2005 and 5.75% by the end of 2010 of all gasoline and diesel, used in transport, measured on energy content basis. Amongst different biofuel pathways available, producing bioethanol and biodiesel from agriculture-derived feedstock appears to be the most feasible, ready-to-market option. The production of such transport biofuels from agricultural feedstock is however constrained by one core limitation – the availability of land, since the use of land for biofuel purposes competes with other, prime applications of land. Devoting enough land to biofuel production is therefore a crucial factor to meet the biofuel targets.

The goal of this report is to investigate the internal production potential of the EU for transport biofuel under different assumptions. Particular emphasis is given on the implications on the land area, which the indicative targets for transport biofuel would have.

The following key conclusions can be highlighted from the analysis in the report:

- √ Meeting the 2% transport biofuel target in 2005 is not likely to cause significant distortions to the agricultural production patterns in the EU. Although, considering the recent production of biofuels – about 0.3% of the automotive gasoline and diesel consumption in the present EU-15 member states and practically no production in the New Acceding and Candidate Countries, substantial efforts will be needed to achieve the 2% target in 2005.
- √ Meeting the 5.75% transport biofuel target in 2010 most probably will require significant changes in the agricultural production patterns in the EU. Considering a larger framework of techno-economic concerns and policy objectives, e.g. security of food supply, implementing such changes might be quite challenging in practice.
- √ On equal terms, the production of bioethanol requires less land than that of biodiesel, due to a larger biofuel yield per hectare from the crops-potential feedstock for bioethanol, compared to the biodiesel crops. Consequently, producing all biofuel as bioethanol would lead to a significant reduction in the land area, needed to meet the transport biofuel targets. Nevertheless, other techno-economic and policy-related drawbacks, e.g. fuel safety and engine performance concerns, crop cultivation specifics, changes in agricultural regulations, etc., are likely to appear in this case.
- √ A potential further enlargement of the EU from 25 countries (consisting of the present EU-15 member states and the 10 New Acceding Countries, which will join the EU in May 2004) with two candidate countries – Bulgaria and Romania would reduce the relative

land area requirements to meet the transport biofuel targets. This would be due to the larger relative biofuel crop potential of these two candidate countries, compared to the present EU-15 member states and the 10 New Acceding Countries.

The above conclusions are drawn, considering the following key preliminary assumptions and limitations:

- √ Biofuel production from agriculture-derived feedstock is only assessed. Biofuel production from ligno-cellulosic material and/or biodegradable waste is not investigated.
- √ The two most appropriate for transport application fuels – bioethanol (used either directly or in the form of bioETBE – Ethyl-Tetrio-Butyl-Ether) and biodiesel – are the only ones assessed.
- √ The potential benefits from by-products of transport biofuel production with regards to other energy, agricultural and other policy objectives, are not taken into account.
- √ The investigation and recommendation of policy options, such as how the land area needed to meet the transport biofuel targets can be made available for this purpose, is not subject to assessment.
- √ The option to increase the EU biofuel supply via imports, which respectively will reduce the internal EU land area requirements for biofuel production, is not considered.

1. BACKGROUND

The EU is heavily dependent upon energy imports. The share of imports in total energy consumption, currently at 50%, could reach 70% by 2030, while the import dependence upon oil might increase up to 90% by 2020. Since world oil reserves are geo-politically concentrated, such import dependence threats the security and diversity of the EU energy supply and in particular – oil supply.

Climate changes, caused by global warming, are another fundamental issue to deal with world-wide. Carbon Dioxide (CO2) is the major GHG that contributes to global warming. In this context, the EU committed under the Kyoto protocol of the United Nations to reduce within 2008-2012 its CO2 emissions by 8% from the 1990 baseline level. On the other hand, with current trends, the CO2 emissions in the EU are projected to grow by 50% between 1990 and 2010, rather than to decline [1].

Transport is a key energy-consuming sector in the EU, responsible for 32% of total energy use. It is almost fully dependent upon oil-derived products – 98% and accounts for 67% of the EU final oil demand. Transport is also a key CO2 generator, responsible for 28% of the CO2 emissions in the EU. In addition, more than 90% of the projected overall increase of the CO2 emissions in the EU will come out from transport [1]. Finding alternatives to secure and diversify the energy supply for transport in an environmentally-friendly way is therefore a key issue for the EU transport, energy and environmental policies.

The EC considers biofuels as a tool that may contribute to achieving the above policy objectives. In this context, two indicative targets for the use of biofuels in transport have been set up. Their reference values are 2% by the end of 2005 and 5.75% by the end of 2010 of all gasoline and diesel[1], used in transport, measured on energy content basis [2]. In fact, these indicative targets face road transport mainly, since other modes of transport (rail, waterborne and air) employ different fuels[2].

Biofuels have a number of strong points, e.g. renewable energy source, ready-to-the-market technology, etc. The core factor, constraining the large application of biofuels, is the availability of feedstock for their production. The feedstock availability is limited by the absolute availability of land. Beside the absolute availability of land, the feasible amount of land, which can be employed for biofuel production, is further restricted by the competition with other, high-priority applications of land. The Common Agricultural Policy (CAP) aims at securing food supply of the EU – a core element in the EU strategy for sustainable development. For this purpose, the CAP regulations try to ensure a reasonable income for farmers. Consequently, a substantial part of the available land is reserved by different

[1] Gasoline and diesel are the key transport fuels, accounting for more than 85% of all transport fuel consumption in the EU [3].
[2] Beside road transport, small quantities of diesel are consumed in waterborne transport only.

regulatory and market forces for food production. In addition, some non-food and non-biofuel applications of land (e.g. for growing flowers, pharmaceutical plants, wood for construction, etc.) normally earn higher profit than biofuels. Respectively, they are more competitive on the land market. Last, but not least, land can be employed for other bioenergy purposes, e.g. production of fuel for Combined Heat and Power (CHP) and/or for electricity generation. All together, these facts mean that the feasible size of land, which can be dedicated to production of transport biofuels, depends on a number of inter-related frameworks.

In this context, the goal of this report is to investigate the internal production potential of the EU for transport biofuel under different assumptions. Particular emphasis is given on the implications on the land area, which the indicative targets for transport biofuel would have. The identification of those land area requirements would allow further analysis how these land areas could be secured for producing transport biofuels, with regard to the alternative applications of land. However, such type of assessment is not performed herein, since it goes beyond the scope and the goal of the report, dealing with non-transport and non-energy issues and frameworks.

2. WORK DESCRIPTION

The report assesses the land area requirements to meet the transport biofuel targets within two enlarged scopes of the EU – 25 countries (EU-25) and 27 countries (EU-27). EU-25 includes the EU 15 member states[3] by the end of 2003 (EU-15), plus the 10 New Acceding Countries (NAC), which will join the EU in 2004[4]. EU-27 includes EU-25 plus 2 Candidate Countries (CC)[5], which may join the EU in 2007.

Referring to the stipulations in [2], the time frame of the analysis is 2005-2010.

Several preliminary assumptions and limitations have to be made explicit.

First, the focus is put on the agriculture-derived production of biofuels only, obtained via fermentation or oil extraction. Biofuel production from ligno-cellulosic material (wood, wood residues, fast growing trees and grass, straw, etc.) and/or all kinds of biodegradable waste, and/or via other technologies, e.g. Gas-To-Liquid (GTL) processing, is not considered. The reason is that currently all these options are at an experimental stage of development. For various techno-economic reasons, their potential market application seems feasible in a medium-term period, probably – beyond 2010 [20], [21].

Considering the typical climate conditions in Europe for agriculture, wheat, potato, sugar beet, rapeseed and sunflower are included in the analysis as potential feed-stocks for transport biofuels.

Only two biofuels with possible application in transport – bioethanol and biodiesel – are investigated, since they appear to be the most feasible by the time horizon of the analysis. Bioethanol and biodiesel can be mixed with conventional gasoline and diesel. When blended in low concentrations, these two biofuels can be handled over the existing infrastructure for liquid fossil fuels and can be used in current engines without engine modifications. Other biofuels with potential use in transport – pure vegetable oil, bio-Methanol, biogas (bio-Methane), bio-DME (bio-DiMethylEther) and bio-Hydrogen, are not considered. Pure vegetable oil has poor market prospective for large-scale application, because its use entails engine modifications[6]. Bio-Methanol, biogas, bio-DME and bio-Hydrogen are obtained mainly from ligno-cellulosic material and/or biodegradable waste, these raw materials are not subject to assessment in this report. Moreover, for various techno-economic reasons, these 4 bio-products are usually considered as feasible industrial-scale fuel options in a more long-term prospective, beyond 2010 [20]. On the other hand, the opportunity to use bioethanol in the form of bio-ETBE (bio-EthylTetrioButylEther) is included. Bio-ETBE is produced from bio-ethanol and isobutylene (a product from crude oil refining), where the bioethanol content

[5] Bulgaria and Romania

[6] A more complete discussion on the transport application of pure vegetable oil can be found in "Unmodified vegetable oil as an automotive fuel", IPTS Report, http://www.jrc.es/home/report/report_main.html, Volume 74 – May 2003.

normally is 47% [2], [20]. Similar to neat ethanol, bio-ETBE can be blended with fossil fuels and if so – there is no need of infrastructure and engine modifications.

Due to the specifics in production pathways, it is assumed that bioethanol is obtained via fermentation of wheat, potato and sugar beet, while biodiesel comes out of oil extraction from rapeseed and sunflower.

[1] specifies only the total energy amount of biofuel that replaces gasoline and diesel. The baseline scenario in this report makes however a distinction between different biofuels connected to which fossil fuels they substitute for. It is assumed that bioethanol (either pure or as ETBE[7]) substitutes gasoline, while biodiesel replaces fossil diesel. The distinction is due to the differences in fuel properties – compatibility or incompatibility of one fuel to another, engine performance, etc. Those differences make difficult the simultaneous comparison of all fuels, e.g. biodiesel with gasoline. Consequently, the biofuel indicative targets are interpreted as meaning equal values for each fuel combination – "bioethanol / gasoline" and "biodiesel / fossil diesel". The corresponding land area requirements are calculated taking into account this distinction.

[1] sets up indicative targets for transport biofuel only for 2005 and 2010. Nevertheless, in order to describe better the process of moving from the starting to the final milestone, virtual intermediate biofuel targets by years (from 2006 to 2009) are included in the report – Figure 1. These intermediate targets identify the land resource, which gradually should be reserved for production of transport biofuels, in order to reach the final biofuel target, assuming a linear growth[8].

Figure 1
Policy-defined and virtual biofuel indicative targets

Year	Biofuel share, %	Source
2005	**2.00**	**Directive 2003/30/EC**
2006	2.75	Virtual intermediate shares, included in the report
2007	3.50	
2008	4.25	
2009	5.00	
2010	**5.75**	**Directive 2003/30/EC**

For the purposes of the report, a detailed forecast about the transport gasoline and diesel consumption in the EU within 2005-2010 is elaborated, based on the projections in [3] – Annex 1. The conversion factors, applied to different fuels assessed in the report, where needed, are given in Annex 2.

Last, but not least, the report makes an analysis of the land area, needed to meet the transport biofuel targets. The estimation and proposal of policy options of how this land area can be made available for production of transport biofuels is not subject to assessment in this

[7] From now on in the report, explicit distinctions between bioethanol and bio-ETBE are made only where needed. Otherwise, all explanations about bioethanol should be considered as fully applicable to bio-ETBE as well.
[8] The initial version of [2] – 2001/0265 (COD), contained the intermediate biofuel milestones from Figure 1. In the final version of the [2], the intermediate biofuel targets have been, however, skipped.

report. Consequently, the report does not deal with eventual changes in the EU frameworks (fuel taxation, agricultural regulations, etc.), if any, which might be necessary to meet the transport biofuel targets.

Finally, the calculations of the land area requirements to meet the transport biofuel targets consider the internal EU production potential only. In an open economy, the EU supply of biofuels can always be increased via imports. Although, the transport biofuel targets have been set up for the EU member states themselves. The eventual import of crops to produce biofuels or the direct import of biofuels to increase the biofuel supply, respectively – to reduce the internal EU land area requirements, are therefore not taken into account.

Several scenarios about the EU biofuel potential and the corresponding land area requirements are constructed. The starting point in all scenarios is the feasible biofuel output of the NAC and CC, ascertained in [17] and [18]. The biofuel production potential of NAC and CC is projected in [17] and [18] in two variants – current potential [Summary of National Forecasts, (SNF)] and optimal potential [Optimal Technical Potential, (OTP)].

The SNF scenario gives a biofuel production potential, based mainly on a summary of national projections in NAC and CC. Where generally accepted local forecasts were not found, the forecasts extrapolate the most favourable past trends within 1996-2000, i.e. land area availability, crop rotation periods, yields, etc. The common point in those projections is that the biofuel potential ensues from a better exploitation of internally available resources (land, labour, technical, financial, know-how). No external resource contribution in terms of funding, technical support and know-how is generally foreseen in the SNF computations.

The OTP scenario assumes an optimal exploration of all resources (land, labour, technical, financial and know-how), which potentially could be made available for producing biofuels, without disturbing[9] the national agricultural balances. The OTP scenario does not take into account the origin of this resource supply (e.g. from EU-15) and the associated costs (the amount of the financial resource required).

In order to evaluate the biofuel production potential of NAC and CC, a forecast about biofuel yields per hectare from different crops is needed. However, the availability of such type of aggregate projections for NAC and CC is generally poorer, than e.g. for EU-15. Therefore, a detailed forecast about biofuel yields per hectare from different crops[10] in NAC and CC, country-by-country, is performed in [17] and [18]. While the SNF estimates ensue from the local projections, the OTP forecast is based on assuming that the yields in NAC and CC will gradually approach the average yields in EU-15.

Considering the land area, which could be made available for producing biofuels in NAC and CC, the land area, needed out of EU-15 to reach the enlarged EU biofuel targets is calculated. For this purpose, projections for biofuel yields per crops assessed in EU-15 are done in the beginning. In contrast with NAC and CC, this forecast gives aggregate average

[9] Generally considered as needs of imports for food purposes

[10] Besides the already mentioned wheat, potato, sugar beet, rapeseed and sunflower, the SNF projections for CC contain also a small production share of bioethanol from maize.

values for EU-15, rather than by countries. This is due to the availability of enough input data with a satisfactory level of disaggregation for EU-15. Next, the calculations of the land area requirements in EU-15 are made in two variants, depending on whether the SNF or the OTP production output of NAC and CC is considered beforehand. For comparative purposes, the land area requirements out of EU-15 are juxtaposed to the EU-15 set-aside land. This is done, since it is sometimes assumed that a large part of the EU-15 set-aside land could potentially be employed for (transport) biofuel production [20].

Finally, the aggregated land area in enlarged EU, required to meet the corresponding transport biofuel targets, is calculated. This is done via summarising the land area in NAC and CC, which can be made available for production of biofuels, with the land area in EU-15, calculated using the approach from the previous paragraph. The enlarged EU requirements of land are again assessed in two cases, depending on whether the SNF or the OTP production output of NAC and CC is used as a starting point.

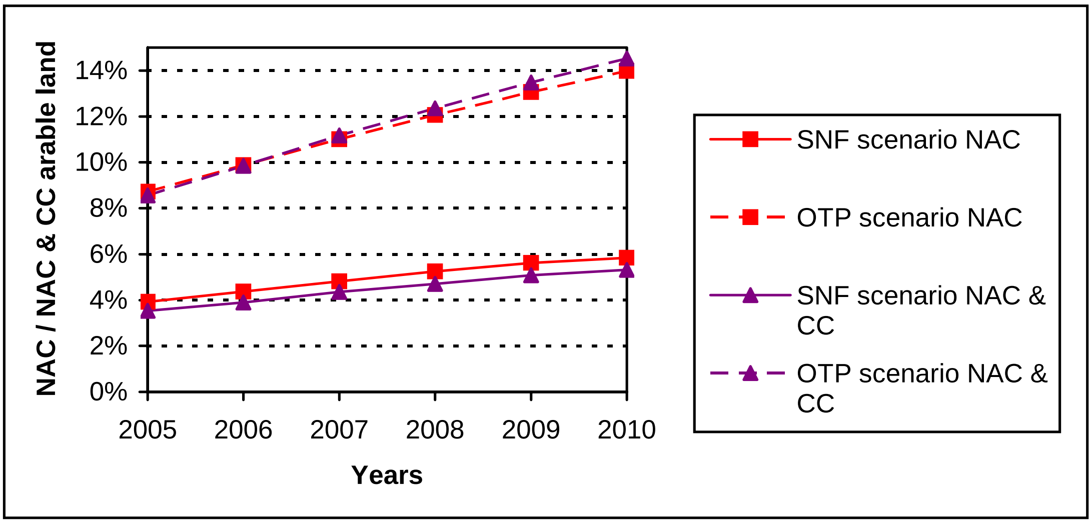
The land area requirements in all scenarios are expressed in relative terms, as a percentage of the corresponding arable land. The arable land is selected as criteria, since it represents the whole area under crop rotation schemes, i.e. used for agricultural production. The projections about the size of the arable land in EU-15, NAC and CC within 2005-2010 are enclosed in Annex 3.

3. FINDINGS

3.1. PRODUCTION POTENTIAL OF NAC AND CC

The land area in NAC and CC, corresponding to the SNF and the OTP scenarios for their biofuel production potential, are presented in Figure 2.

Figure 2
Land area in NAC and CC under the SNF and the OTP scenarios, which could be made available for production of transport biofuels (% of the NAC and CC arable land)



Since the biofuel production potential of NAC and CC is analysed in detail in [17] and [18], only a summary of the most important facts is presented herein. It is projected that the share of land for growing biofuel feedstock in NAC and CC could reach about 14% of their arable land at the maximum. The gradual increase of the land, which could be used for biofuel production, is due to assumed continuous improvement in cultivation patterns and agricultural management. Although, as it has been already pointed out in Section 2, achieving such levels will require significant resource support, mainly – funding, from outside e.g. from EU-15.

Another important conclusion, indicated by Figure 2, is that the relative reserves to expand the production of biofuels in CC are larger than in NAC. One reason for this is that the idle land in NAC is mainly motivated by the poor quality of soil for agriculture, rather than by economic problems. On the contrary, the non-utilisation of land in CC is due exclusively to economic drawbacks, which can be overcome via external financial support, e.g. from EU-15. For the same reason, the reserves to increase the crop yields per hectare in CC are generally larger than the reserves to increase the crop yields in NAC. Nonetheless, despite the identified reserves to increase the land area and the crop yields, the biofuel production potential of NAC and CC appears relatively moderate in general. Thus, NAC and CC could be considered as a positive, but small complement to the enlarged EU biofuel production, rather than as a large reserve of biofuel supply for the EU.

3.2. BIOFUEL YIELDS

The projections about the average transport biofuel yield per crops assessed in EU-15 over the period 2005-2010 are presented in Figure 3[11].

Figure 3
Prospective average biofuel yield from different crops in EU-15 over 2005-2010 (GJ/ha)

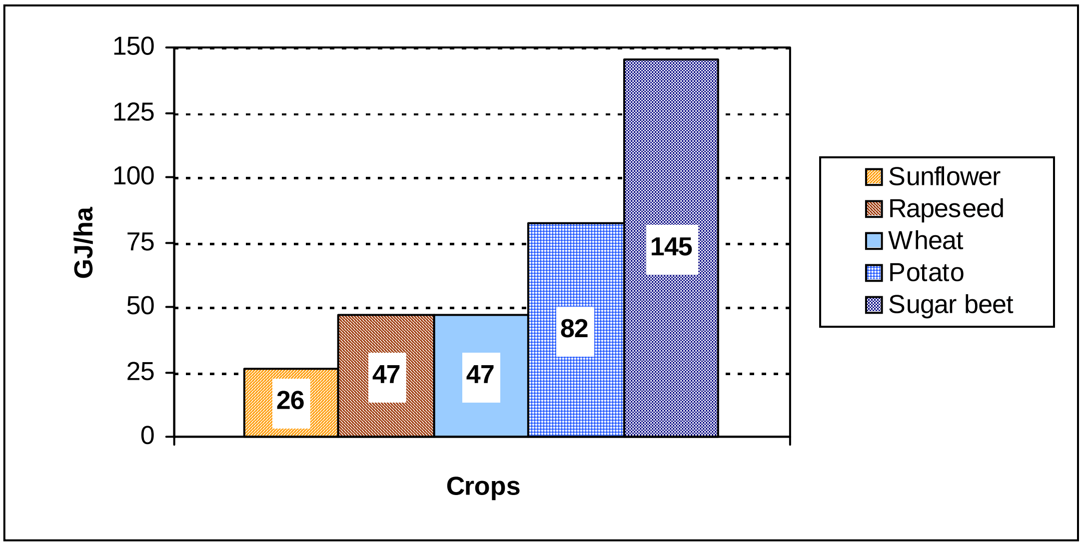


Figure 3 indicates that the bioethanol yield in EU-15 normally is higher than the biodiesel yield. Only under most optimistic estimates, the highest biodiesel yield may reach the amount of the lowest bioethanol yield from the crops considered. On equal terms, this means that a smaller land area will be needed to produce the same amount of transport biofuel, if this biofuel is bioethanol, rather than biodiesel.

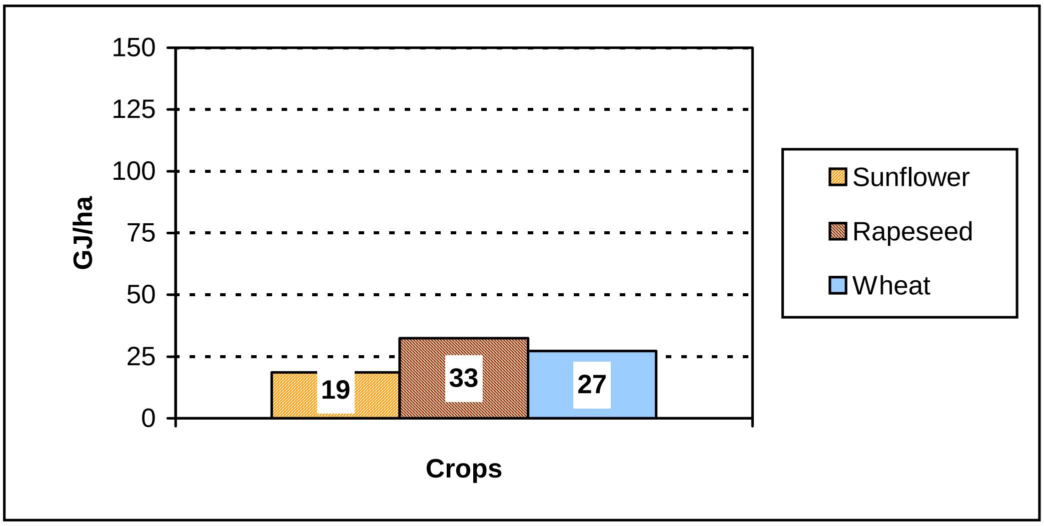
Under prevailing conditions, the average yields from biofuel crops in NAC and CC are projected to be significantly lower, compared to those ones in EU-15 – Figure 4[12]. Whilst for oilseeds the average yields in NAC and CC will represent about 70% of the EU-15 average, for cereals (wheat) this proportion decreases to less than 60%. For this reason, the highest biodiesel yield per hectare in NAC and CC, in contrast with EU-15, is larger than the bio-ethanol revenue from the lowest ethanol-yielding crop – wheat.

On the other hand, the OTP scenario, constructed in [18], assumes that under most optimistic estimates, the oilseed yields in the NAC and CC could reach the EU-15 average by 2010. For bioethanol, the average maximal NAC and CC yields from wheat, potato and sugar beet are feasibly projected to reach 60-65% of the EU-15 average by 2005. This percentage might further increase up to 70-80% by 2010. Consequently, the assumed improvement of oilseed yields in NAC and CC related to reaching the EU-15 average yields, compared to the yields from bioethanol crops, is greater. This is due to the smaller gap between current oilseed yields in NAC and CC, and in EU-15.

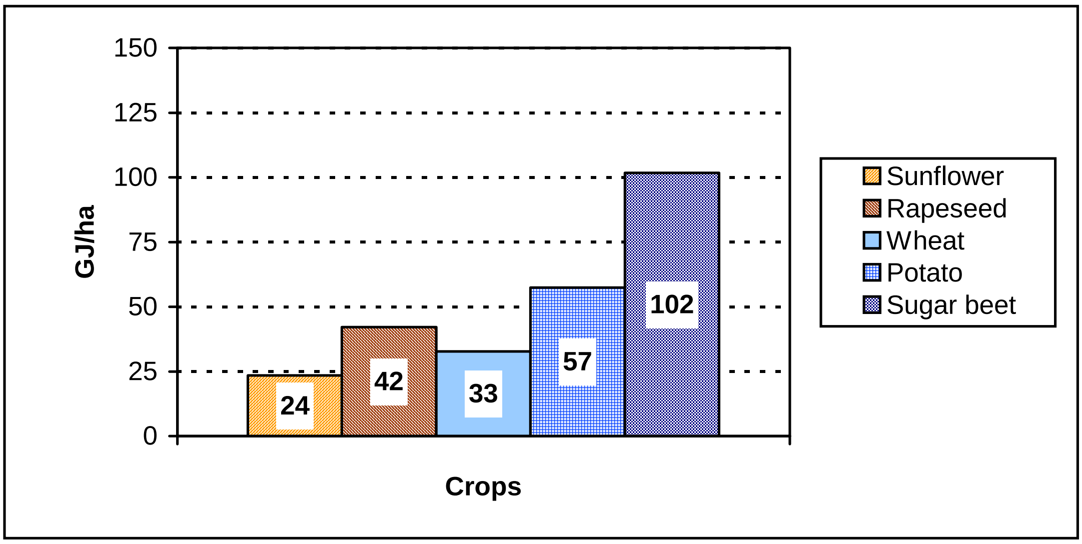
[11] The calculating approach, the values by years and the information sources referred to are given in Annex 4.
[12] The calculating approach, the values by years and the information sources referred to are given in Annex 5.

Figure 4
Prospective average biofuel yield from different crops in NAC and CC over 2005-2009[13] (GJ/ha) – EC estimates



All together, it could be roughly considered that under most optimistic estimates, the average yields from sunflower and rapeseed in NAC and CC over the 2005-2010 period could reach 90% of the EU-15 average yields. For wheat, potato and sugar beet, this proportion could reach 70%. The corresponding approximate absolute biofuel yields by crops in NAC and CC, taken on average for the period 2005-2010, are presented in Figure 5. Figure 5 indicates that the bioethanol yield in the OTP scenarios for NAC and CC normally would be larger than the biodiesel yield – a situation, similar to the EU-15 one.

Figure 5
Projected approximate average biofuel yield from different crops in NAC and CC over 2005-2010 under most optimistic estimates (GJ/ha) – OTP estimates



[13] Projections for 2010 were not found. Projections about potato and sugar beet yields have not been found either. However, the IPTS study "Biofuel production potential of EU-candidate countries" has identified some current values and trends [18]. At present, the potato yield per hectare is about 20 tons – roughly 60% of the EU-15 average. The figures for the sugar beet yields vary substantially from year to year and is difficult to come up with an average figure. Even so, in all cases the prevailing sugar beet yields in NAC and CC are well below the EU-15 yields.

Bering in mind the results from Figure 3 and Figure 5, the scenarios, defined in Section 2, are further refined and complemented. Amongst all potential combinations of crops to meet the transport biofuel targets simultaneously by fuel brands (bioethanol / gasoline and bio-diesel / fossil diesel), for the sake of simplicity 3 variants are selected for further assessment only.

The first scenario ("Upper" case) assumes that the biofuel production will come from the crops with the lowest biofuel yield (wheat for bioethanol and sunflower for biodiesel). In such case, the "Upper" case defines the largest land area requirements to meet the transport biofuel targets simultaneously by fuel brands.

The second scenario ("Lower" case), on the contrary, assumes that the biofuel production will come from the crops with the highest biofuel yield (sugar beet for bioethanol and rapeseed for biodiesel). Consequently, the "Lower" case defines the lowest land area requirements to meet the transport biofuel targets simultaneously by fuel brands. The difference between the "Lower" and the "Upper" scenarios represents the range of variations, where all other potential crop combinations would fall within.

The third scenario is based on the identified here above general yield advantage of bioethanol over biodiesel. This scenario assumes that all biofuel, replacing fossil fuel, is bioethanol, produced from sugar beet – "Lowest" case. Due to this, the "Lowest" scenario defines the absolute least land area requirements to meet the aggregated targets for transport biofuel, without making distinction between fuel brands.

The selection of the above 3 scenarios is based on the use of land only for production of transport biofuels. Nonetheless, within a broader range of techno-economic criteria and policy frameworks, the relative utility of the feedstocks selected may change. For instance, the production of transport biofuels from wheat and rapeseed generates significant quantities of straw as a by-product. Straw can be used for other energy purposes, as a fuel in combined heat & power (CHP) or electricity generation. As a result, straw would improve the security and diversity of the overall energy supply, will lower the GHG emissions and will contribute to other energy policy objectives[14]. Other, non-energy and non-transport policy concerns, e.g. use of by-products as animal feed, suitability to crop rotation, other ecological concerns (e.g. preserving biodiversity) etc., may also favour one or another crop. Thus, the selection of biofuel crops may depend in practice on a number of inter-related policy objectives.

3.3. LAND AREA REQUIREMENTS IN EU-15 WITHIN EU-25

The land area requirements in EU-15 to meet the transport biofuel targets from Figure 1 for EU-25, considering the feasible biofuel production of NAC and CC (Section 3.1), are presented in Figure 6.

[14] More complete discussion on different EU policy targets in the field of renewable energies in general and bioenergy in particular, and their inter-relations can be found in "Land area requirements to meet the targets of the renewable energy policies in the European Union", IPTS Report, Volume 80 – December 2003.

Figure 6
Upper, lower and lowest land area requirements in EU-15 to meet the transport biofuel targets in EU-25, considering the NAC biofuel output (% of the EU-15 arable land)

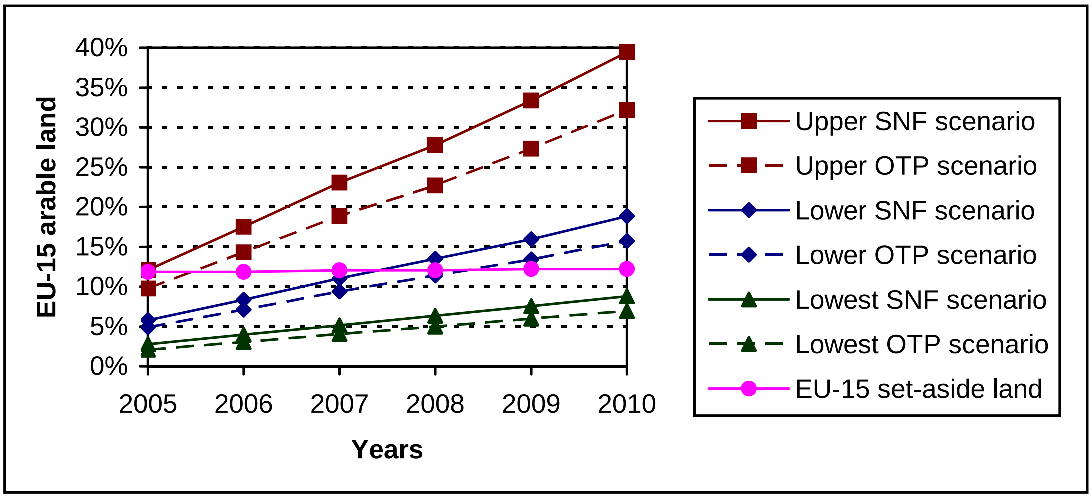


Figure 6 indicates that meeting the 2005 biofuel target simultaneously by fuel brands can be achieved with the usage of a relatively moderate land area – between 5% and 12% of the EU-15 arable land. Although, a much larger area – between 16% and almost 40% of the EU-15 arable land – should be reserved to reach the 2010 biofuel target. If the whole transport biofuel production comes as bioethanol, significant reductions in the land area requirements can occur. In such a case, 7-9 % of the EU-15 arable land will be sufficient to meet the 2010 biofuel target, i.e. a land area, which is less than the EU-15 set-aside land. Unlike the case from Section 3.1, here the gradual increase in the land area, which should be reserved for biofuel production, is due to the smaller growth in crop yields, compared to the combined increase in the gasoline and diesel consumption (affecting the amount of biofuel needed) – Annex 1 and in the biofuel targets (Figure 1). On the other hand, the slower growth in the land area requirements in the OTP scenarios, compared to the SNF cases, is due to the larger relative increase of the OTP crop yields.

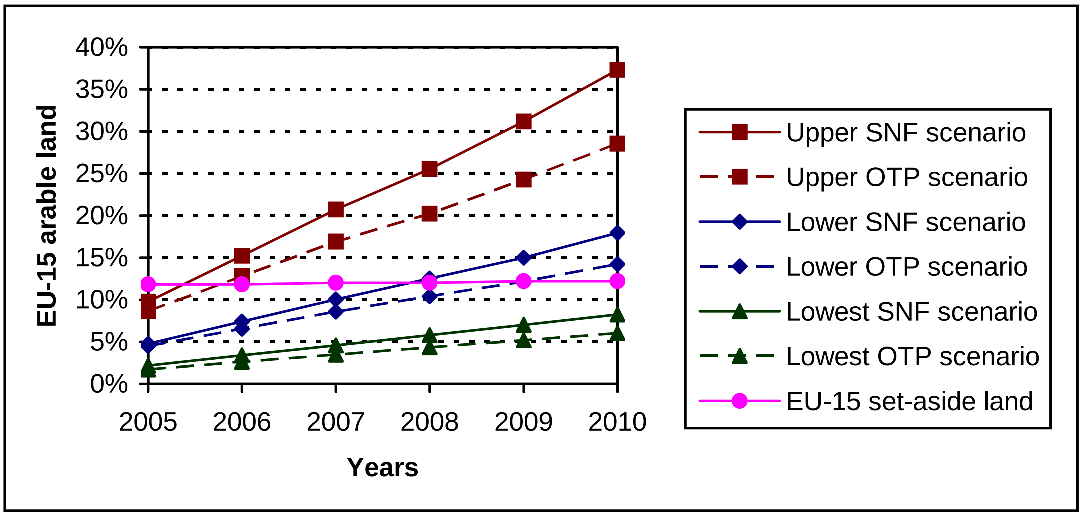
3.4. LAND AREA REQUIREMENTS IN EU-15 WITHIN EU-27

The land area requirements in EU-15 to meet the transport biofuel targets from Figure 1 for EU-27, considering the feasible biofuel production of NAC and CC (Section 3.1), are presented in Figure 7. Basically, the results and the conclusions for EU-27 from Figure 7 are similar to those ones for EU-25 in Figure 6. However, the land area requirements for EU-27 are slightly lower than those ones for EU-25, due to the larger reserves to expand the biofuel production in CC, compared to NAC (see Section 3.1). Another consequence from this larger biofuel potential of CC is that the gap between the OTP and the SNF projections, describing the slowing down growth in the land area requirements, expands faster and becomes wider in the case of EU-27, compared to EU-25. This wider gap is due to the larger relative increase both in the land area for biofuel crops and in the biofuel crop yields in CC, compared to NAC.

Figure 7
Upper, lower and lowest land area requirements in EU-15 to meet the transport biofuel targets in EU-27, considering the NAC & CC biofuel output (% of the EU-15 arable land)

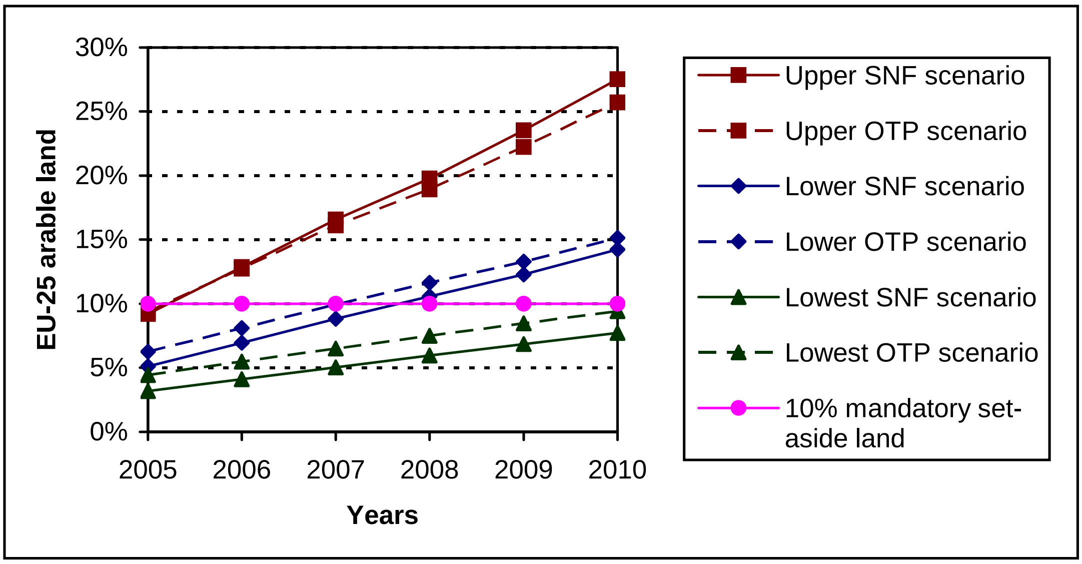


As a result, the reduction in the EU-27 land area requirements, compared to EU-25, in the SNF scenarios is stable over the period 2005-2010, being within the range of 0.5-2%. In the OTP cases however this reduction expands with time, starting from 0.5-1% in 2005 and reaching 1-3.5% in 2010.

3.5. LAND AREA REQUIREMENTS IN EU-25 WITHIN EU-25

The aggregated land area requirements in EU-25 to meet the transport biofuel targets from Figure 1 for EU-25 are presented in Figure 8. In fact, Figure 8 summarises the findings from Figure 2 and Figure 6.

Figure 8
Upper, lower and lowest land area requirements in EU-25 to meet the transport biofuel targets in EU-25, considering the NAC biofuel output (% of the EU-25 arable land)



Similar to the case of Figure 6, meeting the 2005 transport biofuel target simultaneously by fuel brands requires the employment of a relatively moderate land resource – between 5% and slightly more than 9% of the EU-25 arable land. Nevertheless, a much larger land – between 14% slightly more than 27% of the EU-25 arable land – should be reserved for growing biofuel feedstock to meet the 2010 biofuel target. If bioethanol is the only biofuel produced, those land area requirements may drop significantly to 8-9% of the total EU-25 arable land, i.e. a land area, which is similar in size to the assumed set-aside land. The major difference between the findings from Figure 6 and Figure 8 is that within EU-25 the "Lower" and the "Lowest" OTP land area requirements are larger than the SNF requirements. This fact is due to the higher crop yields in EU-15, compared to those ones in NAC. From this point of view, in order to reduce the overall EU-25 land area requirements, it appears more reasonable to put the emphasis on developing biofuel production in EU-15, rather than in NAC. The larger "Upper" SNF land area requirements, compared to the OPT ones, from Figure 8 ensue from the assumed much lower crop yields in NAC, compared to EU-15. This is also reconfirmed by the much larger gap between the OTP and SNF "Upper" estimates, compared to the corresponding "Lower" and "Lowest" forecasts in Figure 6.

3.6. LAND AREA REQUIREMENTS IN EU-27 WITHIN EU-27

The aggregated land area requirements in EU-27 to meet the transport biofuel targets from Figure 1 for EU-27 are presented in Figure 9. In fact, Figure 9 summarises the findings from Figure 2 and Figure 7.

Figure 9
Upper, lower and lowest land area requirements in EU-27 to meet the transport biofuel targets in EU-27, considering the NAC & CC biofuel output (% of the EU-27 arable land)

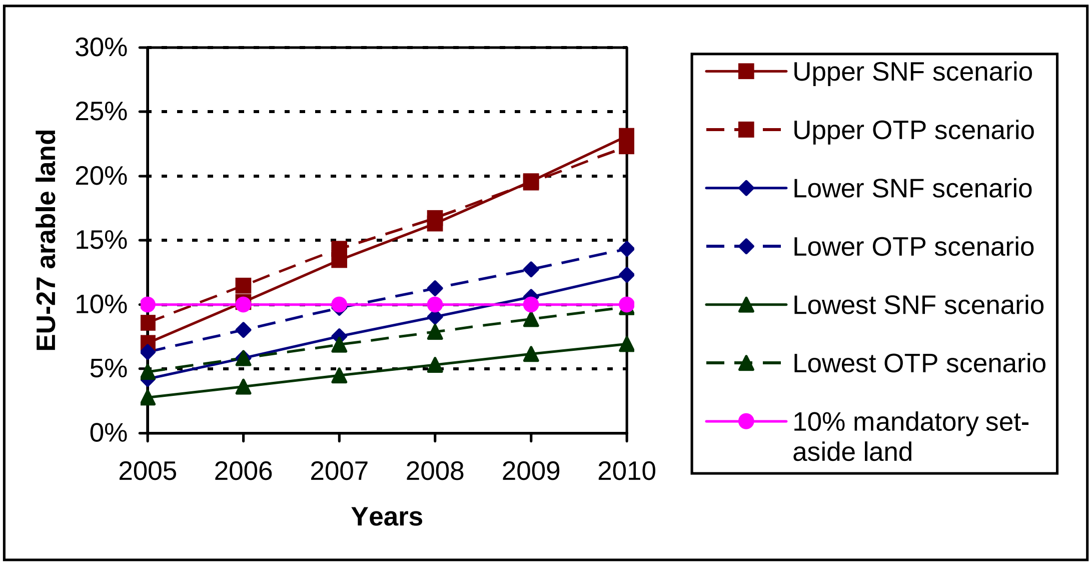


Figure 9 indicates similar trends to those ones, identified in Figure 7 and Figure 8. In general, the land area requirements in EU-27 are lower than those ones in EU-25, due to the larger biofuel expansion potential of CC, compared to NAC. A relatively moderate land area – 4-8.5% of the EU-27 arable land – will be needed to meet the 2005 biofuel target simultaneously by fuel brands. A substantial part of the arable land in EU-27 (12-23%) should be however reserved for biofuel production, in order to meet the 2010 biofuel target. If bioethanol is the only biofuel produced, the land resource needed could be substantially reduced to 7-10%[15] of the EU-27 arable land, which is close to the assumed size of the set-aside land. Within EU-27, the differences between the SNF and the OTP "Upper" projections are smaller, while the gaps between SNF and OTP "Lower" and "Lowest" scenarios are wider, thanks to the larger reserves for increasing the land area and crop yields in CC, compared to NAC.

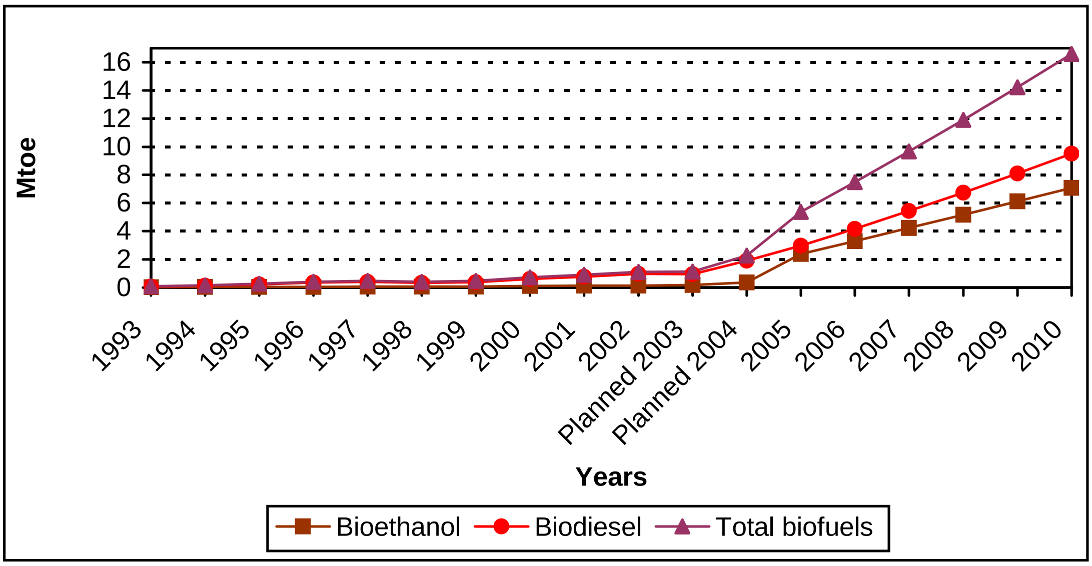
[15] Basically, this is the only land area percentage in EU-27, which is slightly larger than the EU-25 figures, but the actual difference is in fact negligible. The 1% difference, derived from the comparison of the figures from Section 3.5 and Section 3.6, is due to rounding.

4. IMPLICATIONS

Based on the findings from Section 3, several key findings can be drawn.

Meeting the 2005 biofuel target simultaneously by fuel brands would involve relatively moderate land resource. Under optimistic estimates, considering the feasible biofuel potential of NAC and CC, 4-6% of both the EU-15 and the enlarged EU arable land should be reserved for biofuel production. This amount of land for biofuel production would be below the size of the set-aside land, which (as it has been already mentioned) is sometimes assumed as appropriate for developing biofuel production. On the other hand, some recent forecasts state that only about 1.6% of the EU-15 arable land could be dedicated to bioenergy production (including biofuels), if the tax incentives, existing currently in EU-15, would prevail over the period 2005-2010 [10]. Last, but not least, reaching the 2005 indicative target would require significant additional efforts in other sectors. Over the past few years, the biofuel production in EU-15 expanded fast. However, even this large annual growth in biofuel processing capacities and production appears insufficient to meet the 2005 biofuel target, mainly due to the little progress in ethanol – Figure 10[16].

Figure 10
Retrospective (1993-2002) production of biofuels, projected (2003-2004) expansion of biofuel processing capacities and prospective biofuel quantity, needed to meet the policy-defined and virtual indicative biofuel targets in EU-15 – total and by types of biofuels (bioethanol and biodiesel) – (Mtoe)



Sources: [21], [20]

Within enlarged scopes of EU, even more efforts and faster growth in capacities and production would be required, since at present the production of biofuel is almost unknown in

[16] Note that the faster growth between 2002 and 2005 reflects the increase in processing capacities, but not in production. At present, the biofuel processing capacities in EU-15 operate at an average rate of 65% [20].

NAC and CC [17] [18]. Such large growth could be constrained not only by the availability of land for growing biofuel feedstock, but by other factors as well, e.g. building new processing capacities takes time. If such large expansion in the biofuel processing capacities happens simultaneously, it could be delayed also by the lack of enough equipment availability.

Besides the potential issues to deal with, already identified for the 2005 biofuel target, reaching the 2010 biofuel target could be associated with additional potential drawbacks and difficulties. First of all, meeting the 2010 transport biofuel target simultaneously by fuel brands would require a significant land resource. Under most optimistic estimates, considering the feasible biofuel potential of NAC and CC, 14-19% of the EU-15 arable land and 12-15% of the enlarged EU arable land should be reserved for biofuel production. The practical allocation of such large land area for biofuel production could be accompanied by a number of issues to deal with. The first one could be the already mentioned strong competition with other applications of land of prime significance, e.g. for food production. In addition, EU-15 differs with high population densities and lack of significant reserves of free land, suitable for agricultural cultivation. Last, but not least, the size of the arable land area in EU-15 was steadily declining over the past decade – by 0.7% per year on average [7]. All together, these facts could preclude the use of significant land areas in EU-15 for production of biofuels, especially in the "Upper" scenarios. This situation also means that the preferred concentration of the enlarged EU biofuel production in EU-15, rather than in NAC and CC (see Section 3.5), would be difficult for realisation in practice. The cultivation specifics of biofuel plants, i.e. crop rotation periods (e.g. 4-5 years for oilseeds on average), combined with some other concerns (e.g. preserving biodiversity), might also prevent such a large expansion of the land area for biofuel production.

Another factor, which could further complicate reaching the transport biofuel targets by fuel brands, is the trend in the EU transport fuel consumption. Other things being equal, diesel consumption is projected to grow faster than gasoline consumption. As a result, the share of diesel in the EU total transport fuel consumption will expand continuously, at the expense of gasoline[17]. From the point of view of biofuels, this means that relatively more biodiesel will be needed to achieve the biofuel targets. Since biodiesel yield per hectare is normally lower than bioethanol yield, this trend in the EU transport fuel consumption reflects onto an automatic rise in the land area requirements to meet the biofuel targets.

Besides the above direct impacts on the land market and agriculture in the EU, an eventual large-scale production of transport biofuels could have additional, secondary impacts on other sectors. For instance, in order to reduce the land area requirements, the "Lower" scenarios assume that all biodiesel is produced from rapeseed only. Notwithstanding, apart

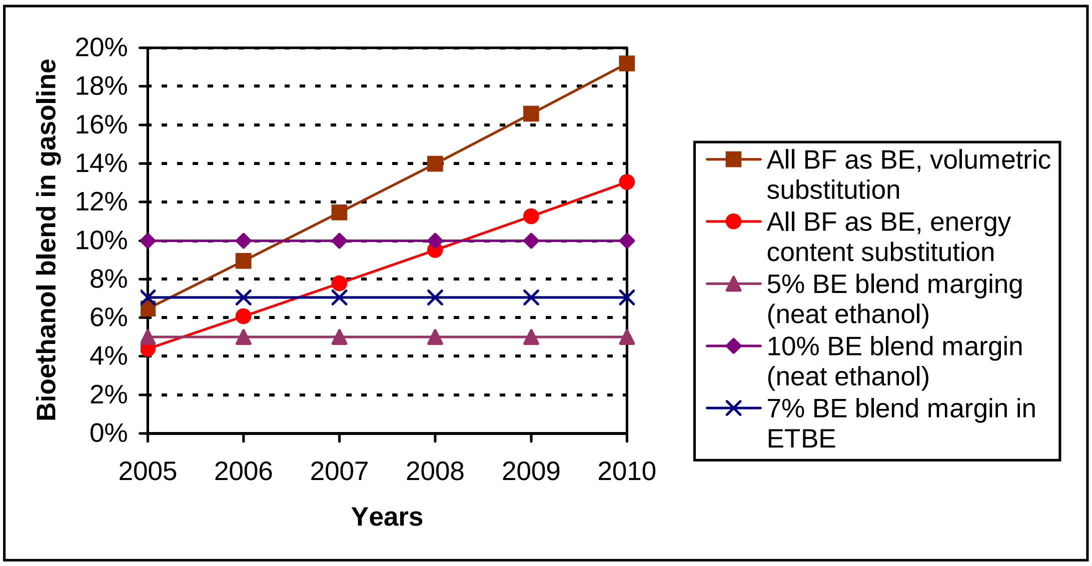
[17] More complete discussion on the growing diesel consumption and declining gasoline use can be found in "Potential limitations of voluntary commitments on CO_2 emission reductions in transport", IPTS report, Volume 79 – November 2003.

from the already mentioned straw, an eventual expanded production of biodiesel from rapeseed will earn significant amounts of glycerol as by-product. At present, there is not enough market demand capacity, which can absorb such large quantities of glycerol. In this aspect, the oleo-chemical industry is afraid that an eventual large-scale application, respectively – production of biodiesel may lead to a destruction of the glycerol market balance [20].

Last, but not least, the above calculations of the land area requirements presume that the whole biofuel produced will be used only in transport. While for bioethanol this assumption could be considered as generally correct, for biodiesel this could not be the exact situation in real market conditions, due to the availability of alternative energy applications of biodiesel. For example, currently 90% of biodiesel production in Italy (the 3rd largest biodiesel producer in the EU, with 19% production share) is employed in stationary heating installations, rather than in transport [20].

With the aim to reduce the land area requirements for transport biofuels, a larger share of bioethanol in the total biofuel production (respectively – consumption) could be considered. In such a case, taking into account the feasible biofuel potential of NAC and CC, maximum 6-9% of the EU-15 arable land and 7-10% of the enlarged EU arable land would be sufficient to achieve the 2010 biofuel target. Although, if all biofuel comes as bioethanol, there would be other techno-economic issues, which should be dealt with. First – if bioethanol is mixed with gasoline only, the bioethanol content in this blended fuel will increase significantly, beyond what is generally agreed as the feasible limit – 5% by volume [23] (Figure 11).

Figure 11
Blending share of bioethanol into gasoline within EU-25[18], if all biofuel is bioethanol (%)



[18] The proportions for EU-25 and EU-27 are basically the same.

Such high bioethanol content will most probably require some engine modifications. Consequently, it will not be possible to use bioethanol as a mass fuel in conventional vehicles any longer. On the other hand, adapting vehicles to the new qualities of this mixed fuel will be always accompanied by additional costs, which will reduce its market attractiveness. For these reasons, the use of bioethanol blends, higher than 10% by volume, is not a wide-spread practice for the moment [16] [23] [24].

Blending bioethanol with gasoline in the form of ETBE does not appear to solve the above drawbacks either. In general, the application of bioethanol as ETBE is preferred, rather than its neat use [23]. This is due to the avoidance of some engine performance penalties of direct ethanol blending, mainly – the increased volatility of the mixed fuel, beyond the limits, defined by current standards [24] [28]. However, the acceptable upper limit of the ETBE content into gasoline is 15% in volume [20] [29]. Considering the ethanol share in ETBE, this means that the bioethanol content in gasoline will be about 7% in volume at the maximum. As it can be seen from Figure 11, this proportion is still far away from the blending share needed, if all biofuel comes as bioethanol. Last, but not least, the feasible quantity of ETBE is constrained by the technological availability of isobutylene, obtained from oil refining [16] [20].

Another solution could be blending bioethanol (up to 10-15%) with fossil diesel, which fuel mix is known as “E-diesel“, “Oxydiesel” or “Diesohol”. At a first glance, this option seems quite appropriate and promising. It would lead to a reduction in the overall land area requirements, because bioethanol yield is normally larger than biodiesel yield. Furthermore, some recent experimental results indicate that Oxydiesel could offer emission savings [20] [27]. Even so, for the moment Diesohol is generally not considered as a convenient transport fuel option. Its key drawback is the very low flash point – about 13°C [23]. Such low flash point poses high explosion risks. Until the problem with the low flash point of Oxydiesel, together with some other performance question-marks (e.g. reduced lubricity and fuel economy, lack of sufficient experimental results about emission performance and health impacts, etc.), is solved, any commercial application of E-diesel appears therefore not feasible [23].

From the supply point of view, an eventual expansion of bioethanol production from sugar beet raises a number of techno-economic complications as well.

First, a significant growth in the land area with sugar beet will be needed to reach the 2010 transport biofuel target. At present, the land area in EU-15, sown with sugar beet for all types of applications, occupies about 2.5% of the EU-15 arable land [8] [10]. In order to meet the 2010 biofuel target in the “Lowest” scenarios, the size of this land area, reserved only for transport biofuel purposes, should be multiplied by a factor of 2 or 3. This extended land area, however, does not include the remaining, non-transport biofuel usages of sugar beet. On the other hand, over the past decade the land area with sugar beet in EU-15 was steadily declining – by 1.6% per year on average [8].

The above situation does not improve when looking at enlarged EU either. Currently, 2.2% of the arable land in enlarged EU is sown with sugar beet [7] [8]. To reach the 2010 transport biofuel target, this land area, dedicated only to biofuel production, should grow by a factor of 3 or 4. Again, this extended land area does not include any other, non-biofuel usages of sugar beet.

The significant growth in the land area with sugar beet to meet the 2010 transport biofuel target is likely to be constrained in practice by several factors. Due to its cultivation specifics, sugar beet should be included into crop rotation schemes, similar to oilseeds. This fact automatically complicates the required huge expansion of the land for sugar beet, since not all arable land and climate conditions in Europe are suitable for sugar beet cultivation[19]. Last, but not least, currently the sugar beet production in EU-15 is heavily subsidised, which does not fall within the line of sustainable rural development and more market-oriented CAP [1] [11]. In this context, different scenarios are discussed about how the CAP in the field of sugar beet cultivation could be adjusted to these policy objectives [11] [12] [13] [14].

At the end, it should be made explicit that the above projections about the land area requirements to meet the transport biofuel targets in the EU are based on some kind of most optimistic preliminary estimates. Agriculture is strongly dependent on the year-by-year climate conditions. Climate changes may substantially affect the actual yields and harvest from biofuel crops in the future. In this context, it should be always kept in mind that the average yields may vary widely from year to year.

[19] Sugar beet is a very intensive crop with specific cultivation requirements – needs good soil and watering. For these reasons, more than 50% of the sugar beet production in EU-15 takes place in France and Germany [10] [14].

5. CONCLUSIONS AND SUGGESTIONS FOR FURTHER RESEARCH

Based on the analysis, performed in the previous sections, the following conclusions about the production of transport biofuel in the EU could be highlighted:

- √ Meeting the 2% transport biofuel target in 2005 is not likely to cause significant distortions to the agricultural production patterns in the EU. Although, considering the recent production of biofuels (0.3% of the EU automotive fuel demand), substantial efforts will be needed to achieve the 2% target in 2005.
- √ Meeting the 5.75% transport biofuel target in 2010 most probably will require significant changes in the agricultural production patterns in the EU. Considering a larger framework of techno-economic concerns and agriculture policy objectives, implementing such changes might be quite challenging in practice.
- √ On equal terms, the production of bioethanol requires less land than that of biodiesel, due to a larger biofuel yield per hectare from the crops-potential feedstock for bioethanol. Consequently, producing all biofuel as bioethanol would lead to a significant reduction in the land area, needed to meet the transport biofuel targets. Nevertheless, other techno-economic and policy-related drawbacks, associated with crop cultivation specifics and agricultural regulations, are likely to appear in this case.
- √ Blending bioethanol with fossil diesel appears as a promising tool to reduce the land area requirements, in view of meeting the transport biofuel targets. A number of technical drawbacks, related to fuel qualities and engine performance, should however be solved before this fuel option becomes feasible in practice.
- √ A potential further enlargement of EU-25 (EU-15 plus 10 NAC) with 2 CC – Bulgaria and Romania, would reduce the relative land area requirements to meet the transport biofuel targets. This would be due to the larger relative biofuel crop potential of these 2 CC, compared to EU-15 and NAC.

Building on the above conclusions, several suggestions for further research could be identified:

- √ Trends in improving processing technologies for ligno-cellulosic feedstock.
- √ Progress in the development of other biofuels (F-T biodiesel, bio-DME, bio-Methanol, biogas, bio-Hydrogen) and related technologies (GTL processing) with potential transport application, in view of their market prospects.
- √ Assessment of the EU biofuel production potential, based on ligno-cellulosic feedstock, with regard to the land area availability in the EU. Due to the specifics of the ligno-cellulosic feedstock, it would be more appropriate for the analysis to consider as a basis for comparisons the Utilised Agriculture Area[20], rather than the arable area.
- √ Assessment of potential technical and technological solutions to overcome the drawbacks of ethanol blending with fossil diesel.

[20] The utilized agricultural area comprises all lands, which can potentially be used for biomass production – arable land, permanent grasslands, permanent crops, crops under glass and kitchen gardens.

Annex 2

Properties of fuels assessed

Fuel	Density (kg/1000 l)	Energy content (MJ/l) [19]	Energy content ratio[24]
Bioethanol	798[25]	21.2	1.472 (BE/FG)
Gasoline	745 [26]	31.2	0.679 (FG/BE)
Biodiesel	880[27]	32.8	1.088 (BD/FD)
Fossil diesel	837.5	35.7	0.919 (FD/BD)

[21] Differences, if any, in the cumulative values are due to rounding.

[22] The forecast for EU-25 is based on the projected in [3] 2010 net values (without the amount of biofuel), discounted for the period 2009-2005 with the average annual growth rate of consumption – 0.9% for gasoline and 2.1% for diesel (Table 4-15 on page 121 in [3]).

[23] Since a forecast for the transport gasoline and diesel consumption in EU-27 is not explicitly performed in [3], some approximations are established for the 2 CC – Bulgaria and Romania. First, the amount of their total transport fuel consumption for 2005 and 2010 is taken from the Tables on page 188 and 208 in [3]. Second, these values for 2005 and 2010 are used to extrapolate the 2006-2009 transport fuel consumption, assuming linear growth. Third, the consumption of gasoline and diesel is derived as a share of total transport fuel consumption – 47.18% and 40.67% respectively. These shares are calculated from the 2010 estimates for total transport fuel, gasoline and diesel consumption in the EU candidate and neighbour countries (Table 3-16 on page 94 in [3]).

[24] The fuel consumption replacement ratio on energy content basis represents the volume of fuel, which is needed to replace 1 litre of another fuel.

Biodiesel yield from 1 ton sunflower (GJ)	14.91	14.91	14.91	14.91	14.91	14.91
Biodiesel yield – sunflower (GJ/ha)	**25.3**	**25.3**	**25.3**	**26.8**	**26.8**	**26.8**

[28] The figures for NAC and CC represent average values from the 1996-2000 retrospective data, given in [7].

[29] Detailed projections about the size of the set-aside land in EU-25 have not been found. However, [10] states that the 10% mandatory set-aside will be kept in the future. On the other hand, the same source assumes that the growth in the voluntary set-aside after the accession of NAC will be limited, due to decoupling of the area payments. Based on these reasons, this report assumes that the size of the overall (mandatory and voluntary) set-aside land, as share of the arable land, will decrease after the enlargement of the EU in 2004. Therefore, the prospective percentage of the set-aside land in EU-25 in this report is taken at the level of the mandatory 10% set-aside.

[30] No projections about the set-aside in EU-27, if any, have been found. Therefore, the approach, applied to EU-25, is extrapolated to EU-27.

[31] Extrapolated from the recent trends (1998-2001), identified from [9].

[32] Extrapolated, based on input data from [16], [20] and [25]

Annex 5

Projections about the average transport biofuel yield (in GJ/ha) from different crops on year-by-year basis in NAC and CC over the period 2005-2010

Biofuel feedstock	2005	2006	2007	2008	2009
Wheat yield (t/ha) [4] [5]	3.58	3.62	3.67	3.71	3.82
Bioethanol yield (l/ton) [16]	350	350	350	350	350
